Abstract. In this paper, we describe a case study on the verification of a real industrial protocol for wireless ATM, called MASCARA. Several tools have been used: SDL has been chosen as the specification language and the commercial tool ObjectGEODE has been used for creating and maintaining SDL descriptions. The IF tool-set has been used for generation, minimization and comparison of system models and verification of expected properties. All specification and verification tools are connected via the IF language, which has been defined as an intermediate representation for timed asynchronous systems as well as an open validation environment. Due to the complexity of the protocol, static analysis techniques, such as live variable analysis and program slicing, were the key to the success of this case study. The results obtained give some hints concerning a methodology for the formal verification of real systems.

1 Introduction

Model checking [CE81,QS82] is by now a well established method for verifying properties of reactive systems. The main reason for its success is the fact that it works fully automatically and it is able to reveal subtle defects in the design of complex concurrent systems. Different academic tools have been developed for supporting these techniques. Not only hardware but also telecommunication industries are beginning to incorporate them as a component of their development process. For example, the commercial SDL design tools ObjectGEODE [Ver96] and TAU [TA99] provide some verification facilities going beyond interactive or random simulation. A major challenge in model checking is dealing with the well-known state explosion problem. This limits its large scale use in practice. In order to limit this problem, different techniques have been developed, such as on-the-fly model-checking [JJS89,Hol90], symbolic model-checking [BCM+90,McM93], partial order reduction [God96,GKP94], abstraction [CGL94,LGS+95], compositional minimization [GS90,KM00] and more recently static analysis reduction [BFG00a]. We try to show here that the right combination of these techniques allows to tackle the verification of large software systems.

We present a detailed report on the verification of an industrial protocol, called MASCARA (Mobile Access Scheme based on Contention And Reservation for ATM) [DP98]. The protocol is a specific medium access control (MAC) protocol, which has been designed for wireless ATM communication and has been developed within the WAND (Wireless ATM Network

* This work was supported by the VIRES project (Verifying Industrial REactive Systems, Esprit Long Term Research Project No.23498)
** VERIMAG is a research laboratory associated with CNRS, Université Joseph Fourier and Institut Nationale Polytechnique de Grenoble
Demonstrator) consortium [WAN96]. SDL [IT94] has been chosen as the specification language by the designers and we have used the commercial tool ObjectGEODE for maintaining the SDL description of the protocol. The IF tool-set [BFG+99b,BFG+99a] has been used for analysis of the protocol. All specification and verification tools of this tool-set have been connected via the IF language, which is an intermediate representation for timed asynchronous systems in an open validation environment. In order to deal with the complexity of the protocol, all the available reduction techniques of the tool have been used in combination to reduce the state graphs of the protocol. The results obtained give some hints on a methodology for the formal verification of large systems.

The paper is organized as follows. Section 2 gives an overview on the MASCARA protocol and a brief description of the IF language and its validation environment. In Section 3, we describe in detail the verification of the protocol. The results are compared and discussed.

2 The Context

2.1 The IF Language and Validation Environment

The IF language [BFG+99a,BFG+99b] has been defined as an intermediate representation for timed asynchronous systems. In IF, a system is described by a set of parallel processes communicating either asynchronously through a set of buffers, or by rendez-vous via a set of gates. Buffers can have various queuing policies (fifo, bag, etc.), can be bounded or unbounded, reliable or lossy, and delayable or with zero delay. Processes are timed automata with urgencies [BST97], extended with discrete variables. Process transitions are triggered by inputs and/or guards and perform variable assignments, and clock settings and signal outputs. An urgency out of eager, delayable, lazy is associated with each transition, defining its priority with respect to time progress. This makes IF very flexible and appropriate on one hand as underlying semantics for high level specification formalisms such as SDL [BKM+01] or ESTELLE used in commercial design tools and on the other hand as an intermediate representation for tool interconnections as it is powerful enough to express the concepts of the languages used in the main verification tools of the domain, such as LOTOS [BB88] and PROMELA [Hol91].

The IF validation environment provides a complete validation tool chain allowing to transform high level SDL descriptions through the intermediate representation into the input formats of several verification tools (see Figure 1) [BFG+00b]:

- **The specification level tools.** IF does not itself provide facilities to edit SDL specifications. For this it relies on the commercial tool-set ObjectGEODE developed by TELELOGIC and supporting SDL, MSC and TTCN. It includes graphical editors and compilers for each of these formalisms and provides step-by-step and random-walk simulation, but also a model-checking facility using observers to help the user to debug an SDL specification. In the verification experiment, ObjectGEODE has mainly been used for maintaining the SDL description of the MASCARA protocol, for visualizing MSCs generated from diagnostic sequences generated by verification tools and for replaying these MSC on the SDL specification to ease error identification.

- **The intermediate level tools.** Based on an API provided by ObjectGEODE, a translator, SDL2IF, generates operationally equivalent IF specification from SDL [BFG+99b]. At the
IF level, a tool called IF2IF implements various static analysis techniques such as dead variable analysis (LIVE), slicing (SLICE), constant propagation and clock reduction. IF2IF transforms with a small cost a given IF description into a semantically equivalent one (with respect to a set of properties) with a reduced model, where a typical factor of reduction observed in many examples is between 1 and 3 orders of magnitude. Any backend tool connected to IF can profit from these reductions. For example, the SPIN tool [Ho91] which has been connected via a translator IF2PML [BDHS00].

- The verification tools. CADP [FGK+96] has been designed as a tool-set for the verification of LOTOS specifications. Its model generation and analysis tools, such as ALDEBARAN and EVALUATOR, have been adapted for IF-specifications and can be used for generation, minimization, comparison of state graphs and verification of properties specified as alternation-free $\mu$-calculus formulas either on-the-fly or on an already generated model. Diagnostic sequences are computed and can be translated into mscs to be displayed in a user friendly manner. Other tools, such as KRONOS [Yov97] for the verification of real-time properties described in TCTL and TGV [FJJV97] for automatic test generation, can work directly on IF specifications.

IF is presently used in several projects of different nature concerned with verification, test case generation, performance analysis and UML modeling; several significant case studies in the domain of verification have already been carried out using IF [BFG+98, BML00]

2.2 The MASCARA Protocol

The MASCARA (Mobile Access Scheme based on Contention And Reservation for ATM) protocol [DP98] is a special medium access control (MAC) protocol designed for wireless ATM (Asynchronous Transfer Mode) communication and developed by the WAND (Wireless ATM Network Demonstrator) consortium [WAN96]. A wireless ATM network extends transparently services to mobile terminals (MT) via a number of geographically distributed access points (AP). The task of the MASCARA protocol is to mediate between APs and MTs via a wireless link. The protocol has a layered structure, where we consider only the highest layer, the MASCARA control layer.
The Purpose of the MASCARA Control Layer (MCL) is to ensure that mobile terminals can initially establish and then maintain an association with an access point with good quality and minimal interruptions as long as the ATM connection is valid. It carries out a periodical monitoring of the current radio link quality (gathering the information about radio link qualities of its neighboring APs to hand-over to in the case of deterioration of the current association link quality) and switching from one AP to another in the hand-over procedure. Since several MTS communicate through a single AP with the ATM core network, MCL is different on the AP and the MT side.

MCL consists of two main parts: dynamic control and static control. We describe in detail the dynamic control part, which we have concentrated on in this case study.

Dynamic Control (DC) The main task of the dynamic control is to set up and release associations and virtual connections. It consists of the following entities: dynamic generic agent, association agent and MAC virtual channel agent.

The dynamic generic agent is the top-level entity of the dynamic control and its task is association management. It dispatches upper layer requests concerning existing associations and connections to the right association agent, manages MAC-layer addresses for the associations, and informs the upper layer about lost associations.

The association agent of an MT and its peer entity in the (to be) associated AP are responsible for managing and supervising a single association. Each association can carry a variable number of connections via virtual channels. The task of the association agent peers is to create the virtual channel agents, map the addresses between the ATM-layer and the MAC-layer connection identifiers and forward requests. Since each MT is at any time associated with at most one AP, there exists one association agent per MT. While, whereas each AP has one association agent for every associated MT.

An MVC agent of an MT and its peer entity in the AP manage a single connection on a virtual channel. Beside address mapping from the ATM-layer to the MAC-layer connection identifiers, the MVC agents are in charge of resource allocation for the connection they manage over the wireless channels.

3 Verification of the MASCARA Protocol

The overall description of the MASCARA protocol which we got is 300 pages of SDL textual code. This makes it impossible to envisage to push the “verify” button on the protocol as a whole. That fact that the descriptions of the lower layers of the protocol were very incomplete made that the protocol was even not simulatable as a whole.

We concentrate on the verification of the MASCARA control layer, for which the SDL description could be made reasonably complete. Here we report on the verification of the dynamic control. Another verification experiment has been carried out on static control [BDHS00]. In this section, we first present the experiment system and the assumptions and simplifications we made. Then, we list some of the correctness properties to be verified and describe in detail the approaches to perform the verification. Finally, we present the verification results and discuss some problems encountered.
Fig. 2. Architectural view of the experimental system

3.1 The Experimental System

**Architecture.** Dynamic control has an interface to the MASCARA management layer (called upper layer here), and exchanges control signals with lower layer entities of the MASCARA protocol. For verification, we abstract all lower MASCARA layers to a pair of buffered communication channels. We have considered these channels as non-lossy, but with a transmission delay that is possibly longer than expected by the timers, so that these channels represent all relevant behaviours of the lower levels of the protocol. The architecture of the SDL model used for verification can be seen in Figure 2 and consists of the following parts:

- **AP Dynamic Control** has itself a hierarchical structure: all signals from outside are received by the **Generic Dynamic Control** process, and either treated directly or forwarded to the relevant **Association Agent**, which on turn, either treats the signal itself or forwards it to the relevant **Virtual Channel (VC)** Agent.
- **MT Dynamic Control** has the same architecture as AP Dynamic Control, but the implemented protocols are of an asymmetric nature: association is always initiated by MT, whereas channel opening can be initiated on both sides, in such a way that MT will always “win” in case of concurrent opening of the same channel on both sides.
- An “**Environment**” process which consists of abstract versions of the upper layer and of the other MASCARA Control entities, in particular steady state control.

We assume that only one MT can be associated and only one connection can be opened, i.e., only one pair of association agents (AAA/MAA) and one pair of MVC agents (AMA/MAA)
are considered, which is sufficient for the correctness properties we have verified.

**Environment.** Verification should be carried out under a general environment with realistic restrictions. As we have not obtained information on the MASCARA upper layer, we considered initially an open system with an unconstrained upper layer, which would allow us to obtain the “most general” verification results. But communication is via unbounded channels as in SDL, leads to infinitely growing channel contents and thus an infinite state model in case that the environment sends requests too often, which is typically the case in “reactive” systems always ready to to treat requests from the environment.

**ObjectGEODE** offers a facility for avoiding this problem which however leads to a drastic restriction of the possible behaviours, allowing a new request from the environment only when no system transition is enabled any more, that is, the previous request has been completely treated. This is not an adequate approach for the MASCARA Protocol which is precisely designed for dealing with several, even conflicting, requests in parallel.

The approach we have chosen to provide a more restricted, but still realistic environment consists in restricting the number of requests it can make per time unit. We assume that within one time unit, no more than “N” requests can be sent by the environment. Considering system transitions as *eager* – that means that time can only progress when no system transition is enabled – this provides an environment suitable for our purpose. The system has never to deal with more than “N” requests “simultaneously” which leads, in the MASCARA protocol, to bounded channel contents. The success of the method depends on the use of a realistic bound. We use N = 4.

Simultaneously means here in the “same time slice”, meaning that the environment can send a new request even if there are previous ones still to be treated. Using Rendez-vous or bounded and blocking channels like in LOTOS or PROMELA leads to similar restrictions as the environment is blocked as soon as all buffers are full. Our solution makes it however easier to exactly qualify the applied restriction.

**The role of time.** This protocol makes use timeouts, essentially to avoid indefinite waiting for a response that will never come. This type of systems can usually be verified as an untimed system, where the occurrence of a timeout is treated as a non-deterministic event. As we use time as a convenient means to slow down the environment, we cannot adopt exactly this solution. We consider

- the transmission delay through the channels between AP and MT as 1 (the value is arbitrary) and all other transmission delays as zero and
- the maximal waiting time for response as 2
- all system transitions as “eager” so that the system is forced to progress until standstill before time can pass.

This has as consequence that responses and corresponding timeouts occur in the same “time slice” and thus can occur in any order, and still time can be used to slow down the environment as it can send in each time slice only a limited number of requests.

### 3.2 Properties

As it is often the case, the designers of the system did not provide us with requirements that the system must satisfy. Therefore, we considered generic properties such as deadlocks. And
for each request from the environment (such as association, deassociation, connection opening, connection release,...) a set of “response properties”, where in a first time we verified very weak properties, such as “potential response”, and the more the system became debugged, the more we strengthened them. As an example, we show the strongest response property considered for “association request”.

**Association Establishment** This property refers to association establishment between an MT and an AP which is obtained by a four-way handshake protocol initiated by MT. The signals between the system and the upper layer are:
- the request for association establishment (“a_req”) from the upper layer to MT.
- the response to association request (“a_confc (rc)”) by MT to the upper layer.
- the indication of association establishment (“a_ind”) AP to the upper layer.

The response property we considered for checking the correctness of the association establishment, is the following one:

“Any association request received by the MT is eventually followed by an association confirmation with either a negative or a positive result. In the second case, an association indication has already been or will eventually be emitted by the AP.”

**Expression of Properties** We have used several formalisms for the expression of properties:

1. We expressed some properties by sets of temporal logic formulas. Temporal logics such as Computational Tree Logic (CTL)[CGP99] and Linear Temporal Logic (LTL)[MP92] are widely used. The model-checker EVALUATOR is based on the use of the alternation-free μ-calculus[Koz83] which is more expressive, but more difficult to use. However, there exist macros going beyond the modalities of CTL or LTL, such that most properties can be expressed conveniently at least by an expert. For verification (see Section 3.3), we decomposed the above correctness criterion into simpler properties (Table 2). The following formula expresses the requirement **Req1** of this table, where “allF”, “inev” and “TRUE” are macros which should be intuitive enough.

\[
\text{all} [a_{\text{req}}](\text{inev} < a_{\text{cnf}_{-}f} > \text{TRUE})
\]

2. **CTL** and **LTL** are not powerful enough to express all useful properties. Moreover, they are difficult to use by a non expert for the expression of complex state and event sequencing properties often required for protocols, especially if they are not covered by the set of macros. Finite automata are another formalism for the expression of properties which is powerful yet relatively easy to use. In our tools we use labeled transition systems (LTS), where the transition labels are a set of observable events, which are in our case a subset of the signal input and output events, possibly with their parameters. Figure 3 shows on the left side an LTS expressing **Req1** of Table 2 and on the right side a refinement of it. This refined version, which corresponds more to the really expected behaviour, is easier to express by an LTS than by a temporal logic formula.

---

1 A return code is attached with the response signal which indicates positive (e.g. success) or negative (e.g. failed, already associated or no response) result of the corresponding association request.
3. We have tried to apply so called “visual verification” which gives often very satisfactory results. It consists in “computing” the exact property of the system with respect to a set of observable events: the (completely constructed) state-graph is minimized with respect to an appropriate equivalence relation, such as observational[Mil80] or safety[BFG+91] equivalence. In this particular protocol, the obtained minimal state-graphs were most of the time still too complicated to be inspected visually. The reason for this seems to be the counting effect introduced by limiting the number of simultaneous requests (to 4).

4. We have used Message Sequence Charts (MSC). Nevertheless, we have not written them ourselves in order to express negations of safety properties, but our tools generated them from diagnostic sequences, showing the violation of some property formulated in another formalism. In Figure 5 an example of such a “diagnostic MSC” can be found.

### 3.3 Verification Methodology

Given a property $\varphi$ and a system $S$, described as a parallel composition of a number of subsystems $S_i$, the goal of model checking is to verify whether $S_1 \parallel \cdots \parallel S_n \models \varphi$ holds.

It is well-known that the size of the state graph grows exponentially with the number of components $S_i$ (and also the number of variables). For the MASCARA protocol, even if only a single association and a single connection is considered, the state space is too large to be analyzed without application of any reduction technique.

We combined the use of all reduction techniques available in our tools and applied them in the order depicted in Figure 4. We explain the results observed using the different techniques in the following paragraphs.

**Static Analysis Reduction Techniques:** *static analysis techniques* is applied at the program level to reduce the number of states and transitions of the model associated with the specification and thus make model checking feasible.
1. Dead variable analysis transforms an IF specification into an equivalent one by adding systematic reset statements of “dead” variables. A variable is “dead” at some control point if its value is not used before it is assigned again. This transformation preserves all event-oriented properties of the original specification while the global state space and consequently the exploration time are reduced.

2. Program slicing automatically extracts portions of a program relevant for a specific property, called slicing criterion: for example, a set of variables or signals at program points of interest for the given correctness property. The reduction is obtained by eliminating program parts which do not influence the slicing criterion. There is a different model for each property (or a set of properties). This transformation preserves safety properties depending only on the slicing criterion, while it results smaller IF-program.

These reductions are performed on the structural program level description of the system, before model generation and their complexity is completely unproblematic. They can, and should, be always applied, independently of the verification method or tool being used later on.

**Partial Order Reduction** [God96,GKPP94] is a method which consists in verifying properties of a concurrent system without exploring all interleavings of concurrent executions of independent transitions. It preserves properties on orderings of events as long as they are considered dependent. A simple version of this method has been implemented in the IF toolset. In order to use partial order reduction jointly with compositional techniques, we need to consider all signal input from the “environment” as dependent, no matter the property to be verified. It is well-known that partial order reduction allows a significant reduction of the size of the state-graph, and should therefore always be applied during generation or traversal of the model.
Atomicity Reduction A well-known reduction method consists in considering sequences of internal steps as "model steps". This is correct as long as each sequence contains at most one read or write action of a global variable and at most one modification of observable variables.

SDL greatly facilitates the use of this method: all transitions start by reading a signal from the process's message buffer, and then execute a set of actions consisting in local assignments and signal outputs to buffers of other processes. All properties we consider are expressed in terms of signal inputs and outputs and in MASCARA there are never two observable outputs sent within a single SDL transition; thus we can consider complete SDL transitions as atomic steps. The reduction obtained by atomicity reduction is in general tremendous. As it is applied by default in the step-function of the IF tool-set, we can however not show its effect.

On-the-Fly Model Checking: In "on-the-fly" model checking [JJ89b,FM91,Hol91] verification is performed during a possibly exhaustive traversal of the model. This method is very helpful, in particular at the first stage of verification for the debugging of the initial specification, as it exposes fast many errors and omissions, even of systems which cannot be verified completely. It should be noted, however, that only for very simple safety properties, the underlying model of the on-the-fly analysis has the same size as the system model alone. For more complex properties, on-the-fly verification explores a model which can be significantly bigger than the system model alone, and some of the advantage of not storing transitions vanishes. In the particular case of the MASCARA protocol, there was no verification of a non-trivial property that we could do on-the-fly, but for which we could not generate the state graph.

Compositional Verification: We have applied two different types of compositional verification. The first one is based on property decomposition [Kur94], and the second one is based on compositional generation of a state graph minimized with respect to a behavioral equivalence [GS90]. For the application of both methods, we split the system into smaller functional parts, namely, AP dynamic control and MT dynamic control.

1. a) decompose a global property of a system into a set of local properties of the considered subsystems;
   b) verify each local property on the corresponding subsystem — using a particular environment representing an abstraction of the remaining subsystems.
All safety properties which hold on a small configuration hold also on the complete system. This method is very convenient to use, under the condition that the global properties can be decomposed and that it is sufficient to include a very abstract view of the neglected subsystems. For example, Req1, Req2, Req3a and Req3b of Table 2 below, are such local properties of MT which can be verified on a state graph, generated by abstracting the AP part almost as the Chaos process (making sure however that it is not too active). see Table 1.

2. a) generate the state graph of each subsystem (AP and MT) separately, considering the same weak abstraction of the other subsystem as in the first method, and reduce it with respect to weak bisimulation using the ALDEBARAN tool;
b) apply parallel composition on the reduced models (as communication between AP and MT is via a pair of buffers, these buffers are the global variables of the system and need to be considered as such for parallel composition [KM00])

c) verify the global correctness properties on the generated global model.

This method preserves all safety properties on observable events. Req3 of Table 2 below, for example, can be evaluated on the state graph DC1 mentioned in Table 1.

The first method allows to work with smaller models than the second one as no abstraction of the global state graph need to be constructed. Unfortunately, it can sometimes be quite difficult to find an appropriate decomposition of properties and to provide a useful abstraction of the “non-considered parts” of the system. For example, the decomposition of Req3 into Req3a and Req3b is only correct if the communication channels between AP and MT can be considered as reliable. Notice that the second method does not necessarily rely on a correct environment abstraction [GS90], but this variant is not implemented in our tool for systems communicating through asynchronous buffers.

3.4 Complexity

Table 1 gives an overview of a subset of the state graphs we have generated using different reduction techniques and allows to compare their sizes.

Execution Time With respect to execution time, the following observation can be made: execution times are roughly proportional to the size of the generated graphs, which means that the different reduction methods do not introduce any significant overhead. For static analysis reduction this result is not surprising. For partial order reduction it is the case because we use a simple static dependency relation. Table 1 shows only minimization results for relatively small graphs (AP4a and MT4a) so that minimization time is small anyway. Nevertheless, it can be seen that minimization for observational equivalence is more expensive than for safety equivalence, as the computation of the transitive closure transition relation “\(\tau \star a\star\)” is required (where \(\tau\) represents a non-observable and \(a\) an observable transition).

State Graph Size We can see that application of dead variable analysis (LIVE) and partial order reduction (PO) alone reduces the original state graph by 1 to 2 orders of magnitude. The combination of LIVE and PO gives more than the combined reduction of each of these techniques applied in isolation. Notice that for AP, the efficiency of PO and LIVE are about the same, whereas for MT, LIVE performs better; in other case studies we also had the situation where PO performed better, so that one can say that with a negligible cost, applying them together, most of the time, one obtains good reduction (here 3 orders of magnitude).

Obviously the reduction obtained by the application of slicing depends heavily on the considered properties, and it is impossible to make general statements. For the considered system, we get similar reductions when slicing according to the 4 main sub-protocols (1 to 2 additional orders of magnitude), where connection opening is slightly more complicated than the others (it involves more signal exchanges than the others), and thus we get a bit less reduction.

It was impossible to generate the state graph of the global system as a whole, thus we started to consider AP and MT in isolation (see first two parts of the Table 1). Finally, we were able

to compositionally generate a reduced model of the global system using compositional generation, under the condition to use both LIVE and partial order reduction for the generation of the subsystems.

3.5 Verification Results

We did a large number of verification experiments with increasing complexity. Initially, many deadlocks were found which were mainly due to the interaction the different “request/response” sub-protocols. It should also be mentioned that the feature of implicit (that is silent) discarding unexpected signals in SDL made the analysis of the generated diagnostic sequences of deadlock traces more difficult. Using a different translation from SDL to IF, this problem has disappeared.

As we had obtained almost no information on the environment of the MASCARA layer, we considered initially the case where the request from the environment can be sent in any order. This lead to a number of error traces which we considered to be “probably because of too loose assumptions on the environment” and we added corresponding restrictions for subsequent verifications. The state graphs mentioned in Table 1 have been obtained using the most restrictive environment.

<table>
<thead>
<tr>
<th>Property: Association Establishment</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Req1.</strong> After reception of an association request by MT, an association confirmation with either positive or negative return value will be eventually sent by MT to the upper layer.</td>
<td>TRUE</td>
</tr>
<tr>
<td><strong>Req2.</strong> After reception of an association request by MT, there exists an execution path where an association confirmation with positive return value is sent by MT to the upper layer.</td>
<td>TRUE</td>
</tr>
<tr>
<td><strong>Req3.</strong> Whenever the association confirmation with positive return value is sent by MT, an association indication will be or has already been sent by AP to the upper layer.</td>
<td>FALSE</td>
</tr>
<tr>
<td><strong>Req3a.</strong> Whenever AP receives the third handshake message (MPDU_MT.AP.addr.received), it will eventually send the fourth handshake message (MPDU_AP_MT.Assoc.ack) to MT, and an indication of the association (a.ind) to the upper layer.</td>
<td>TRUE</td>
</tr>
<tr>
<td><strong>Req3b.</strong> Whenever MT receives the fourth handshake message (MPDU_AP_MT.Assoc.ack) from AP, it will eventually send a successful confirmation (a.conf) to the upper layer.</td>
<td>FALSE</td>
</tr>
</tbody>
</table>

**Table 2.** Properties and Verification results for Association Establishment

Table 2 lists the verification results for the properties concerning association establishment. We performed the verification in an incremental manner, starting with weak properties, weaker than those mentioned in the table, for each subsystem (AP and MT), and finally ending up with the strong properties of the table which we verified either on the relevant subsystem or on the reduced version of the global system.
The local property Req3b (as well as the global property Req9) does not hold. A diagnostic was produced by the tool EVALUATOR. Figure 5 gives an MSC scenario of such a trace. Its analysis shows that this violation occurs when a deassociation request is sent before the association has been confirmed. In case of a deassociation request, a negative association confirmation is sent to the environment independently of the success of the handshake protocol with AP, and this is a correct behaviour. Thus, Req3a should be replaced by the following weaker requirement (which holds):

When MT receives an MPDU.AP_MT_Assoc_ack from AP, it will eventually a successful confirmation (a cnf_suc) to the upper layer, except if it has already received or meanwhile receives a deassociation request from the upper layer.

4 Conclusion and Perspectives

In this paper, we have presented an experiment report on the verification of an industrial ATM protocol. The aim of this verification was much more the experimentation and improvement of the verification facilities of the IF tool-set and the analyze of the difficulties occurring with such a big protocol and their solution rather than the actual verification of the protocol. We
believe that we have at least partially succeeded. The main difficulties that we encountered
together with some responses or some to-do list are the following ones, in the order in which
they appeared:

1. **How to extract a subsystem from a large SDL description?** (such as a single
   layer from a whole protocol stack) The fact that we did not enlarge verification from the
   initially considered sub-system to a larger subsystem is partially due to the fact that it is
   such a time consuming hand-work to cut large SDL descriptions in pieces, or to recombine
   separately modified subsystems at a later stage. Hopefully, the integration of on one hand
   UML oriented features in SDL design tools, which allow to trace interface changes, and
   on the other hand static analysis methods allowing to “cut out” subsystems in a clean
   manner, will eliminate this problem.

2. **How to get reasonable abstraction of the neglected parts of the system?** In a
   protocol stack,
   - the lower layers can often easily be abstracted by communication channels with par-
     ticular properties: they may be reliable or lossy, ordered or unordered, delayable or
     immediate.
   - The upper layers can often be considered as unconstraint or only weak order con-
     straints are necessary, a part from the fact that the flooding of the system with
     infinitely fast sequences of requests must be avoided in order to make state space
     exploration tractable. Fortunately, for the verification of safety properties it is always
     reasonable to limit the number of requests of the upper layer per time unit.
   For other subsystems which are not related in such a simple way with the subsystem
   under study, slicing is one way to get a simplified description, but in our example this
   was not sufficient. General abstraction techniques as those implemented in the InVest tool
   [BLO98] will be connected with if.

3. **How to get requirements?** A part from “deadlock-freedom”, there exist only few
   “generic” properties which must hold for any system. Communication protocols, can of-
   ten be viewed as reactive systems which must react “in an appropriate way” to a number
   of “requests” from the environment; moreover this is true for every sub-layer of the pro-
   tocol. In an ideal case, the designer should be able to help in expressing the appropriate
   “response properties”. In absence of help we used the following strategy, which turned
   out to work quite well: we started with very weak response properties and strengthened
   them as long as they hold. When we found a violated property, we analyzed a number of
   diagnostic sequences (or graphs) produced by the model-checkers in order to find out if
   it was likely to be
   - a real problem of the system,
   - a too loose environment
   - or a too strong property
   and we made corresponding changes.

4. **How to express properties?** For simple properties, temporal logic is very convenient,
   but for more complicated ones, for example taking into account a number of exceptions un-
   der which the desired response need not to occur, temporal logic is cumbersome. Labeled
   transition systems allow to express more complicated properties on message exchanges.
   msCs express the existence of sequences with certain characteristics, and are therefore
more appropriate for the representation of “bad scenarios” or “never claims”. We believe that a generalization of MCOs, such as Live Sequence Charts [DH99], could be very useful.

5. **How to analyze negative verification results?** In the case where the violation of a property is due to (a set of) execution sequences, we translated these sequences into message sequence charts which we than replayed on the SDL specification using a facility of ObjectGEODE. This was convenient as long the sequences were not too long. Using an abstraction criterion makes the sequences shorter, but introduces non-determinism, which is another source of complexity, and hides sometimes away the problematic point. We found that only once we had a good understanding of the protocol (which should be the case for the designers), we could detect subtle errors with a reasonable effort.

6. **How far can we go with system verification?** We hope that we have demonstrated that using an appropriate strategy, we can verify automatically reasonably small subsystems or components of large systems. For the verification of global properties of large systems, automatic verification using state space enumeration, combined with whatever reduction strategies, seems out of reach. To go a step further we applied two approaches — out of the large number of compositional approaches proposed in the literature — which could be applied using the facilities of our tool-set.

- compositional construction of a state-graph reduced with respect to some equivalence relation. Our results show that this method will probably not scale, unless the interfaces between the subsystems are very concise, or we can provide automatic means for getting precise enough abstractions of large parts of a system.
- compositional verification based on property decomposition. We believe that this method can scale, even if there are at least two problems which can make its application difficult:
  - the decomposition of a global system with a large number of subsystems can be very hard (we applied it to a system with only two subsystem and a very simple communication structure)
  - as for the first method an abstraction of the environment of the considered subsystem is needed, even if one can hope that less concise abstractions are enough.

**Acknowledgments**

We would like to thank Marius Bozga, Lucian Ghirvu and Laurent Mounier for fruitful discussion and kind help during the verification experiment.
