

# Preemptive Job-Shop Scheduling using Stopwatch Automata

Yasmina Abdeddaïm      Oded Maler\*

## Abstract

In this paper we show how the problem of job-shop scheduling where the jobs are preemptible can be modeled naturally as a shortest path problem defined on an extension of timed automata, namely stopwatch automata where some of the clocks might be frozen at certain states. Although standard verification problems on stopwatch automata are known to be undecidable, we show that due to well-known properties of optimal schedules, the shortest path in the automaton belongs to a finite class of acyclic paths where transitions occur at integer points in time, and hence the problem is solvable. We present several algorithms and heuristics for finding the shortest paths in such automata and test their implementation on numerous benchmark examples.

## 1 Introduction

In [AM01] we have described a first step in a research programme intended to re-formulate scheduling problems using (timed) automata-based formalisms — the reader is referred to [AM01] for the motivation and to [AM99, AGP99, NTY00, NY00, BFH<sup>+</sup>01a] for other recent results in this spirit. In this framework the runs of the timed automaton correspond to feasible schedules and finding a time-optimal schedule amounts to finding the shortest path (in terms of elapsed time) in the automaton. In [AM01] we have shown how this works nicely for the job-shop scheduling problem which can be modeled by a certain class of *acyclic* timed automata, having finitely many qualitative<sup>1</sup> runs. Each such qualitative run is an equivalence class of a non-countable number of quantitative runs, but as we have shown, one of those (a “non-lazy” run which makes transitions as soon as possible) is sufficient to find the optimum over the whole class. These observations allowed us to apply efficient search algorithms over single configurations of clocks rather than work with zones.

In this work we extend these results to preemptible jobs, i.e. jobs that can use a machine for some time, stop for a while and then resume from where they stopped. Such situations are common, for example, when the machines are computers. While extending the framework of [AM01] to treat this situation we encounter two problems:

1. The corresponding class of automata goes beyond timed automata because clocks are stopped but not reset to zero when a job is preempted. General reachability problems for such stopwatch automata (also known as *integration graphs*) are known to be undecidable [KPSY99].

---

\*VERIMAG Centre Equation, 2, av. de Vignate 38610 Gières, France, [Oded.Maler@imag.fr](mailto:Oded.Maler@imag.fr)

<sup>1</sup>By a qualitative run of a timed automaton we mean a sequence of states and transitions without metric timing information.

2. Due to preemption and resumption, which corresponds to a loop in the underlying transition graph, the obtained automata are cyclic (unlike the non-preemptive case) and they have potentially an *infinite* number of qualitative runs.

We will show however that these problems can be overcome for the class of stopwatch automata that correspond to preemptible job shop problems, and that efficient algorithms can be constructed.

The rest of the paper is organized as follows. In section 2 we give a short introduction to the preemptive job-shop scheduling problem including a fundamental property of optimal schedules. In section 3 we recall the definition of stopwatch automata and show how to transform a job-shop specification into such an automaton whose runs correspond to feasible schedules. In section 4 we describe efficient algorithms for solving the shortest-path problem for these automata (either exactly or approximately) and report the performance results of their prototype implementation on numerous benchmark examples.

## 2 Preemptive Job-Shop Scheduling

The Job-shop scheduling problem is a generic resource allocation problem in which common resources (“machines”) are required at various time points (and for given durations) by different tasks. The goal is to find a way to allocate the resources such that all the tasks terminate as soon as possible (or “minimal make-span” in the scheduling jargon). We consider throughout the paper a fixed set  $M$  of resources. A *step* is a pair  $(m, d)$  where  $m \in M$  and  $d \in \mathbb{N}$ , indicating the required utilization of resource  $m$  for time duration  $d$ . A *job specification* is a finite sequence

$$J = (m_1, d_1), (m_2, d_2), \dots, (m_k, d_k) \tag{1}$$

of steps, stating that in order to accomplish job  $J$ , one needs to use machine  $m_1$  for  $d_1$  time, then use machine  $m_2$  for  $d_2$  time, etc.

**Definition 1 (Job-Shop Specification)** *Let  $M$  be a finite set of resources (machines). A job specification over  $M$  is a triple  $J = (k, \mu, d)$  where  $k \in \mathbb{N}$  is the number of steps in  $J$ ,  $\mu : \{1..k\} \rightarrow M$  indicates which resource is used at each step, and  $d : \{1..k\} \rightarrow \mathbb{N}$  specifies the length of each step. A job-shop specification is a set  $\mathcal{J} = \{J^1, \dots, J^n\}$  of jobs with  $J^i = (k^i, \mu^i, d^i)$ .*

In order to simplify notations we assume that each machine is used exactly once by every job. We denote  $\mathbb{R}_+$  by  $T$ , abuse  $\mathcal{J}$  for  $\{1, \dots, n\}$  and let  $K = \{1, \dots, k\}$ .

**Definition 2 (Feasible Schedules)** *Let  $\mathcal{J} = \{J^1, \dots, J^n\}$  be a job-shop specification. A feasible schedule for  $\mathcal{J}$  is a relation  $S \subseteq \mathcal{J} \times K \times T$  so that  $(i, j, t) \in S$  indicates that job  $J^i$  is busy doing its  $j^{\text{th}}$  step at time  $t$  and, hence, occupies machine  $\mu^i(j)$ . We let  $T_j^i$  be the set of time instants where job  $i \in \mathcal{J}$  is executing its  $j^{\text{th}}$  step, i.e.  $T_j^i = \{t : (i, j, t) \in S\}$ .<sup>2</sup> A feasible schedule should satisfy the following conditions:*

1. Ordering: if  $(i, j, t) \in S$  and  $(i, j', t') \in S$  then  $j < j'$  implies  $t < t'$  (steps of the same job are executed in order).

---

<sup>2</sup>We may assume further that  $T_j^i$  is can be decomposed into a countable number of intervals.

Figure 1: Two schedule  $S_1$  and  $S_2$  visualized as the machine allocation function  $\alpha$  and the task progress function  $\beta$ .

2. Covering: For every  $i \in \mathcal{J}$  and  $j \in K$

$$\int_{t \in T_j^i} dt \geq d^i(j)$$

(every step is executed).

3. Mutual Exclusion: For every  $i, i' \in \mathcal{J}$ ,  $j, j' \in K$  and  $t \in T$ , if  $(i, j, t) \in S$  and  $(i', j', t) \in S$  then  $\mu^i(j) \neq \mu^{i'}(j')$  (two steps of different jobs which execute at the same time do not use the same machine).

Note that we allow a job to occupy the machine *after* the step has terminated. This helps in simplifying the automata but has no effect on the *optimal* solution. The *length*  $|S|$  of a schedule is the maximal  $t$  over all  $(i, j, t) \in S$ . We say that a step  $j$  of job  $i$  is *enabled* in time  $t$  if  $t \in \mathcal{E}_j^i = (\max T_{j-1}^i, \max T_j^i]$ . The *optimal job-shop scheduling problem* is to find a schedule of a minimal length. This problem is known to be NP-hard [GJ79]. From the relational definition of schedules one can derive the following commonly used definitions:

1. The *machine allocation function*  $\alpha : M \times T \rightarrow \mathcal{J}$  stating which job occupies a machine at any time, defined as  $\alpha(m, t) = i$  if  $(i, j, t) \in S$  and  $\mu^i(j) = m$ .
2. The *task progress function*  $\beta : \mathcal{J} \times T \rightarrow M$  stating what machine is used by a job is at a given time, defined as  $\beta(i, t) = m$  if  $(i, j, t) \in S$  and  $\mu^i(j) = m$ .

These functions are partial — a machine or a job might be idle at certain times.

**Example 1:** Consider  $M = \{m_1, m_2, m_3\}$  and two jobs  $J^1 = (m_1, 3), (m_2, 2), (m_3, 4)$  and  $J^2 = (m_2, 5)$ . Two schedules  $S_1$  and  $S_2$  appear in Figure 1. The length of  $S_1$  is 9 and it is the optimal schedule. As one can see, at  $t = 3$   $J^1$  preempts  $J^2$  and takes machine  $m_2$ .

We conclude this section with a reformulation of a well-known result concerning optimal preemptive schedules which will be used later. In essence this result formalizes the following

Figure 2: Removal of inefficiency,  $J_1 \prec J_2 \prec J_3$ .

two intuitive observations: 1) *When jobs can be preempted and resumed at no cost, there is no reason to delay a step not being in a conflict with another.* 2) *Two jobs that keep on preempting each other do not contribute to the general progress.*

**Definition 3 (Conflicts and Priorities)** *Let  $S$  be a feasible schedule. We say that job  $i$  is in conflict with job  $i'$  on machine  $m$  in  $S$  (denoted by  $i \not\ll_m i'$ ) when there are two respective steps  $j$  and  $j'$  such that  $\mu^i(j) = \mu^{i'}(j') = m$  and  $\mathcal{E}_j^i \cap \mathcal{E}_{j'}^{i'} \neq \emptyset$ . We say that  $i$  has priority over a conflicting job  $i'$  (denoted by  $i \prec_m i'$ ) if it finishes using  $m$  before  $i'$  does, i.e.  $\max T_j^i < \max T_{j'}^{i'}$ .*

Note that conflicts and priorities are always induced by a schedule  $S$  although  $S$  is omitted from the notation.

**Definition 4 (Efficient Schedules)** *A schedule  $S$  is efficient if for every job  $i$  and a step  $j$  such that  $\mu^i(j) = m$ , job  $i$  uses  $m$  during all the time interval  $\mathcal{E}_j^i$  except for times when another job  $i'$  such that  $i' \prec_m i$  uses it.*

The following is a folk theorem, whose roots go back at least to [J55] with some reformulation and proofs in, for example, [CP90, PB96].

**Theorem 1 (Efficiency is Good)** *Every preemptive job-shop specification admits an efficient optimal schedule.*

**Sketch of Proof:** The proof is by showing that every inefficient schedule  $S$  can be transformed into an efficient schedule  $S'$  with  $|S'| \leq |S|$ . Let  $I$  be the first interval when inefficiency occurs for job  $i$  and machine  $m$ . We modify the schedule by letting  $i$  use  $m$  at  $I$  and if there was another job  $i'$  such that  $i \prec_m i'$  occupying  $m$  at that time, we give it the time slot liberated by  $i$ . Since anyway  $i'$  terminates the step after  $i$ , it is not delayed. We can then proceed to the next inefficiency until all are eliminated.  $\blacksquare$

As an illustration consider the schedules appearing in Figure 2 with  $J_1 \prec_m J_2 \prec_m J_3$  and where  $J_2$  is enabled in the interval  $[t_1, t_2]$ . The first inefficiency in  $S_1$  is eliminated in  $S_2$  by letting  $J_2$  use the free time slot before the arrival of  $J_1$ . The second inefficiency occurs when  $J_3$  uses the machine while  $J_2$  is waiting, and it is removed in  $S_3$ . The last inefficiency where  $J_3$  is waiting while  $m$  is idle is removed in  $S_4$ .

The significance of this result is that it reduces the set of candidates for optimality from the non-countable set of feasible schedules to the finite set of efficient schedules, each of which

corresponds to a fixed priority relation.<sup>3</sup> There are potentially  $kn!$  priority relations but only a fraction of those needs to be considered because when  $i$  and  $i'$  are never in conflict concerning  $m$ , the priority  $i \prec_m i'$  has no influence on the schedule.

### 3 Stopwatch Automata

Timed automata [AD94] are automata augmented with continuous clock variables whose values grow uniformly at every state. Clocks are reset to zero at certain transitions and tests on their values are used as pre-conditions for transitions. Hence they are ideal for describing concurrent time-dependent behaviors. There are however situations, preemptive scheduling being among those, in which we need to measure the overall accumulated time that a systems spends in some state. This motivated the extension of the model to have clocks with derivative zero at certain states. Such automata were called Integration Graphs in [KPSY99] where they were studied as models for the Duration Calculus [CHR91]. The results in [KPSY99] included the undecidability of the reachability problem for these automata, and a decision procedure for some special sub-classes based on reducing the problem into linear constraint satisfaction. Similar automata were also investigated in [MV94] and in [CL00] where an implementation of an approximate verification algorithm was described.

#### Definition 5 (Stopwatch Automaton)

A stopwatch automaton is a tuple  $\mathcal{A} = (Q, C, s, f, \mathbf{u}, \Delta)$  where  $Q$  is a finite set of states,  $C$  is a finite set of  $n$  clocks,  $\mathbf{u} : Q \rightarrow \{0, 1\}^n$  assigns a constant slope to every state and  $\Delta$  is a transition relation consisting of elements of the form  $(q, \phi, \rho, q')$  where  $q$  and  $q'$  are states,  $\rho \subseteq C$  and  $\phi$  (the transition guard) is a boolean combination of formulae of the form  $(c \in I)$  for some clock  $c$  and some integer-bounded interval  $I$ . States  $s$  and  $f$  are the initial and final states, respectively.

A clock valuation is a function  $\mathbf{v} : C \rightarrow \mathbb{R}_+ \cup \{0\}$ , or equivalently a  $|C|$ -dimensional vector over  $\mathbb{R}_+$ . We denote the set of all clock valuations by  $\mathcal{H}$ . A configuration of the automaton is hence a pair  $(q, \mathbf{v}) \in Q \times \mathcal{H}$  consisting of a discrete state (sometimes called “location”) and a clock valuation. Every subset  $\rho \subseteq C$  induces a reset function  $\text{Reset}_\rho : \mathcal{H} \rightarrow \mathcal{H}$  defined for every clock valuation  $\mathbf{v}$  and every clock variable  $c \in C$  as

$$\text{Reset}_\rho \mathbf{v}(c) = \begin{cases} 0 & \text{if } c \in \rho \\ \mathbf{v}(c) & \text{if } c \notin \rho \end{cases}$$

That is,  $\text{Reset}_\rho$  resets to zero all the clocks in  $\rho$  and leaves the others unchanged. We use  $\mathbf{1}$  to denote the unit vector  $(1, \dots, 1)$ ,  $\mathbf{0}$  for the zero vector and  $\mathbf{u}_q$  for  $\mathbf{u}(q)$ , the derivative of the clocks at  $q$ .

A step of the automaton is one of the following:

- A discrete step:  $(q, \mathbf{v}) \xrightarrow{0} (q', \mathbf{v}')$ , where there exists  $\delta = (q, \phi, \rho, q') \in \Delta$ , such that  $\mathbf{v}$  satisfies  $\phi$  and  $\mathbf{v}' = \text{Reset}_\rho(\mathbf{v})$ .
- A time step:  $(q, \mathbf{v}) \xrightarrow{t} (q, \mathbf{v} + t\mathbf{u}_q)$ ,  $t \in \mathbb{R}_+$ .

---

<sup>3</sup>This might explain the popularity of priority-based approach in computer scheduling.

A *run* of the automaton starting from  $(q_0, \mathbf{v}_0)$  is a finite sequence of steps

$$\xi : (q_0, \mathbf{v}_0) \xrightarrow{t_1} (q_1, \mathbf{v}_1) \xrightarrow{t_2} \dots \xrightarrow{t_l} (q_l, \mathbf{v}_l).$$

The *logical length* of such a run is  $l$  and its *metric length* is  $|\xi| = t_1 + t_2 + \dots + t_l$ . Note that discrete transitions take no time.

Next we construct for every job  $J = (k, \mu, d)$  a timed automaton with one clock such that for every step  $j$  with  $\mu(j) = m$  there are three states: a state  $\bar{m}$  which indicates that the job is waiting to start the step, a state  $m$  indicating that the job is executing the step and a state  $\tilde{m}$  indicating that the job is preempted after having started. Upon entering  $m$  the clock is reset to zero, and measures the time spent in  $m$ . Preemption and resumption are modeled by transitions to and from state  $\tilde{m}$  in which the clock does not progress. When the clock value reaches  $d(j)$  the automaton leaves  $m$  to the next waiting state. Let  $\bar{M} = \{\bar{m} : m \in M\}$ , and let  $\bar{\mu} : K \rightarrow \bar{M}$  and  $\tilde{\mu} : K \rightarrow \tilde{M}$  be auxiliary functions such that  $\bar{\mu}(j) = \bar{m}$  and  $\tilde{\mu}(j) = \tilde{m}$  whenever  $\mu(j) = m$ .

**Definition 6 (Stopwatch Automaton for a Job)** Let  $J = (k, \mu, d)$  be job. Its associated timed automaton is  $\mathcal{A} = (Q, \{c\}, u, \Delta, s, f)$  with  $Q = P \cup \bar{P} \cup \tilde{P} \cup \{f\}$  where  $P = \{\mu(1), \dots, \mu(k)\}$ ,  $\bar{P} = \{\bar{\mu}(1), \dots, \bar{\mu}(k)\}$  and  $\tilde{P} = \{\tilde{\mu}(1), \dots, \tilde{\mu}(k)\}$ . The slope is defined as  $u_q = 1$  when  $q \in P$  and  $u_q = 0$  otherwise.<sup>4</sup> The transition relation  $\Delta$  consists of the following types of tuples

type	$q$	$\phi$	$\rho$	$q'$	
1) begin	$\bar{\mu}(j)$	true	$\{c\}$	$\mu(j)$	$j = 1..k$
2) pause	$\mu(j)$	true	$\emptyset$	$\tilde{\mu}(j)$	$j = 1..k$
3) resume	$\tilde{\mu}(j)$	true	$\emptyset$	$\mu(j)$	$j = 1..k$
4) end	$\mu(j)$	$c \geq d(j)$	$\emptyset$	$\bar{\mu}(j+1)$	$j = 1..k-1$
end	$\mu(k)$	$c \geq d(k)$	$\emptyset$	$f$	

The initial state is  $\bar{\mu}(1)$ .

The automata for the two jobs in Example 1 are depicted in Figure 3.

For every automaton  $\mathcal{A}$  we define a *ranking function*  $g : Q \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$  such that  $g(q, v)$  is a lower-bound on the time remaining until  $f$  is reached from  $(q, v)$ :

$$\begin{aligned} g(f, v) &= 0 \\ g(\bar{\mu}(j), v) &= \sum_{l=j}^k d(l) \\ g(\mu(j), v) &= g(\bar{\mu}(j), v) - \min\{v, d(j)\} \\ g(\tilde{\mu}(j), v) &= g(\bar{\mu}(j), v) - \min\{v, d(j)\} \end{aligned}$$

In order to obtain the timed automaton representing the whole job-shop specification we need to compose the automata for the individual tasks. The composition is rather standard, the only particular feature is the enforcement of mutual exclusion constraints by forbidding global states in which two or more automata are in a state corresponding to the same resource  $m$ . An  $n$ -tuple  $q = (q^1, \dots, q^n) \in (M \cup \bar{M} \cup \tilde{M} \cup \{f\})^n$  is said to be *conflicting* if it contains two distinct components  $q^i$  and  $q^{i'}$  such that  $q^i = q^{i'} = m \in M$ .

<sup>4</sup>Note that the slope at state  $\bar{m}$  can be arbitrary because clock  $c$  is *inactive* in this state: it is reset to zero without being tested upon leaving  $\bar{m}$ .

Figure 3: The automata corresponding to the jobs  $J^1 = (m_1, 4), (m_2, 5)$  and  $J^2 = (m_1, 3)$ .

**Definition 7 (Mutual Exclusion Composition)** Let  $\mathcal{J} = \{J^1, \dots, J^n\}$  be a job-shop specification and let  $\mathcal{A}^i = (Q^i, C^i, u^i, \Delta^i, s^i, f^i)$  be the automaton corresponding to each  $J^i$ . Their mutual exclusion composition is the automaton  $\mathcal{A} = (Q, C, \mathbf{u}, \Delta, s, f)$  such that  $Q$  is the restriction of  $Q^1 \times \dots \times Q^n$  to non-conflicting states,  $C = C^1 \cup \dots \cup C^n$ ,  $s = (s^1, \dots, s^n)$ ,  $f = (f^1, \dots, f^n)$ . The slope  $\mathbf{u}_q$  for a global state  $q = (q^1, \dots, q^n)$  is  $(u_{q^1}, \dots, u_{q^n})$  and the transition relation  $\Delta$  contains all the tuples of the form

$$((q^1, \dots, q^i, \dots, q^n), \phi, \rho, (q^1, \dots, p^i, \dots, q^n))$$

such that  $(q^i, \phi, \rho, p^i) \in \Delta^i$  for some  $i$  and the two global states  $(q^1, \dots, q^i, \dots, q^n)$  and  $(q^1, \dots, p^i, \dots, q^n)$  are non-conflicting.

Part of the automaton obtained by composing the two automata of Figure 3 appears in Figure 4. We have omitted the preemption/resumption transitions for  $m_1$  and  $m_3$  as well as some other non-interesting paths.

A run of  $\mathcal{A}$  is *complete* if it starts at  $(s, \mathbf{0})$  and the last step is a transition to  $f$ . From every complete run  $\xi$  one can derive in an obvious way a schedule  $S_\xi$  such that  $(i, j, t) \in S_\xi$  if at time  $t$  the  $i^{\text{th}}$  component of the automaton is at state  $\mu(j)$ . The length of  $S_\xi$  coincides with the metric length of  $\xi$ .

**Claim 2 (Runs and Schedules)** Let  $\mathcal{A}$  be the automaton generated for the preemptive job-shop specification  $\mathcal{J}$  according to Definitions 6 and 7. Then:

1. For every complete run  $\xi$  of  $\mathcal{A}$ , its associated schedule  $S_\xi$  is feasible for  $\mathcal{J}$ .

Figure 4: The global timed automaton for the two jobs.

2. For every feasible schedule  $S$  for  $\mathcal{J}$  there is a run  $\xi$  of  $\mathcal{A}$  such that  $S_\xi = S$ .

**Corollary 3 (Preemptive Scheduling and Stopwatch Automata)**

The optimal preemptive job-shop scheduling problem can be reduced to the problem of finding the shortest path in a stopwatch automaton.

The two schedules of Figure 1 correspond to the following two runs (we use the notation  $\perp$  to indicate inactive clocks):

$$\begin{aligned}
 S_1 : \\
 & (\bar{m}_1, \bar{m}_2, \perp, \perp) \xrightarrow{0} (m_1, \bar{m}_2, 0, \perp) \xrightarrow{0} (m_1, m_2, 0, 0) \xrightarrow{3} (m_1, m_2, 3, 3) \xrightarrow{0} (\bar{m}_2, m_2, \perp, 3) \xrightarrow{0} \\
 & (\bar{m}_2, \tilde{m}_2, \perp, 3) \xrightarrow{0} (m_2, \tilde{m}_2, 0, 3) \xrightarrow{2} (m_2, \tilde{m}_2, 2, 3) \xrightarrow{0} (\bar{m}_3, \tilde{m}_2, \perp, 3) \xrightarrow{0} (\bar{m}_3, m_2, \perp, 3) \xrightarrow{0} \\
 & (m_3, m_2, 0, 3) \xrightarrow{2} (m_3, m_2, 2, 5) \xrightarrow{0} (m_3, f, 2, \perp) \xrightarrow{2} (m_3, f, 4, \perp) \xrightarrow{0} (f, f, \perp, \perp)
 \end{aligned}$$

$$\begin{aligned}
 S_2 : \\
 & (\bar{m}_1, \bar{m}_2, \perp, \perp) \xrightarrow{0} (m_1, \bar{m}_2, 0, \perp) \xrightarrow{0} (m_1, m_2, 0, 0) \xrightarrow{3} (m_1, m_2, 3, 3) \xrightarrow{0} (\bar{m}_2, m_2, \perp, 3) \xrightarrow{2} \\
 & (\bar{m}_2, m_2, \perp, 5) \xrightarrow{0} (\bar{m}_2, f, \perp, \perp) \xrightarrow{0} (m_2, f, 0, \perp) \xrightarrow{2} (m_2, f, 2, \perp) \xrightarrow{0} (\bar{m}_3, f, \perp, \perp) \xrightarrow{0} \\
 & (m_3, f, 0, \perp) \xrightarrow{4} (m_3, f, 4, \perp) \xrightarrow{0} (f, f, \perp, \perp) \xrightarrow{0}
 \end{aligned}$$

Some words are in order to describe the structure of the job-shop timed automaton. Ignoring the *preempt* and *resume* transitions, the automaton is *acyclic* and its state-space admits a natural partial-order. It can be partitioned into levels according to the number of *begin* and *end* transitions from  $s$  to the state. There are no staying conditions (invariants) and the automaton can stay forever in any given state. Recall that in a timed automaton, the transition graph might be misleading, because two or more transitions entering *the same* discrete state, e.g. transitions to  $(m_3, f)$  in Figure 4, might enter it with different clock valuations, and hence lead to different continuations. Consequently, algorithms for verification and quantitative analysis might need to explore all the nodes in the unfolding of the automaton into a tree. Two transitions outgoing from the same state might represent a choice of the scheduler, for example, the two transitions outgoing from  $(\overline{m}_2, m_2)$  represent the choice of whether or not to preempt  $J^2$  and give machine  $m_2$  to  $J^1$ . On the other hand some duplication of paths are just artifacts due to interleaving, for example, the two paths leading from  $(\overline{m}_1, \overline{m}_2)$  to  $(m_1, m_2)$  are practically equivalent.

Another useful observation is that from every (preemptive or non-preemptive) job-shop specification  $\mathcal{J}$  one can construct its reverse problem  $\mathcal{J}'$  where the order of every individual job is reversed. Every feasible schedule for  $\mathcal{J}'$  can be transformed easily into a feasible schedule for  $\mathcal{J}$  having the same length. Doing a forward search on the automaton for  $\mathcal{J}'$  is thus equivalent to doing a backward search on the automaton for  $\mathcal{J}$ .

## 4 Shortest Paths in Stopwatch Automata

In order to find shortest paths in stopwatch automata we will take advantage of Theorem 1 to restrict the search only to runs whose corresponding schedules are efficient.

**Definition 8 (Efficient Runs)** *A run of a stopwatch automaton constructed according to Definitions 6 and 7 is efficient if all discrete transitions are taken as soon as they are enabled, and all conflicts are resolved according to a fixed priority relation.*

To be more precise, let  $J_1$  and  $J_2$  be two jobs which are in conflict concerning machine  $m$  and let  $J_1$  be the one with the highest priority on  $m$ . Table 4 depicts all the potential conflict situations and how they are resolved.

In situations 1, 2, 4, and 5  $J_1$  is waiting for the machine which is not occupied and so it takes it. Such situations could have been reached, for example, by a third job of higher priority releasing  $m$  or by  $J_1$  finishing its prior step and entering  $\overline{m}$ . Situation 3 is similar but with  $J_1$  occupying  $m$  and hence has to be preempted to reach situation 2. Situation 6, where  $J_1$  is preempted and  $J_1$  is executing, contradicts the priority and is not reachable. In situations 7 and 8,  $J_1$  is executing and no preemption action is taken. Finally situation 9 violates mutual exclusion.

The restriction to efficient runs makes the problem decidable: we can just enumerate all priority relations, derive the schedules implied by each of them and compare their lengths. The search algorithm that we employ on the unfolding of the automaton generates priorities *on the fly* whenever two jobs come into conflict. In the example of Figure 3 the first conflict is encountered in state  $(\overline{m}_2, m_2)$  and from there we may choose between two options, either to continue with time passage or preempt  $J_2$ . in the first case we fix the priority  $J_2 \prec J_1$  and let  $J_2$  finish without considering preemption anymore while in the second case the priority is

	state	action	new state	remark
1	$(\bar{m}, \bar{m})$	start 1	$(m, \bar{m})$	
2	$(\bar{m}, \tilde{m})$	start 1	$(m, \tilde{m})$	
3	$(\bar{m}, m)$	preempt 2	$(\bar{m}, \tilde{m})$	
4	$(\tilde{m}, \bar{m})$	resume 1	$(m, \bar{m})$	
5	$(\tilde{m}, \tilde{m})$	resume 1	$(m, \tilde{m})$	
6	$(\tilde{m}, m)$			(impossible)
7	$(m, \bar{m})$	(continue)	$(m, \bar{m})$	
8	$(m, \tilde{m})$	(continue)	$(m, \tilde{m})$	
9	$(m, m)$			(impossible)

Table 1: Resolving conflicts when  $J_1 \preceq_m J_2$ .

$J_1 \prec J_2$ , we move to  $(\bar{m}_2, \tilde{m}_2)$  and the transition back to  $(\bar{m}_2, m_2)$  becomes forbidden. From there we can only continue to  $(m_2, \tilde{m}_2)$  and let the time pass until  $J_1$  finishes to use  $m_2$ .

To formalize this we define a *valid successors* relation over tuples of the form  $(q, \mathbf{x}, \Pi, \theta)$  where  $(q, \mathbf{x})$  is a global configuration of the automaton,  $\Pi$  is a (partial) priority relation and  $\theta$  is the total elapsed time for reaching  $(q, \mathbf{x})$  from the initial state. When there is no immediate transition enabled in  $(q, \mathbf{x})$  we have

$$Succ(q, \mathbf{x}, \Pi, \theta) = \{(q, \mathbf{x} + \mathbf{u}_q t, \Pi, \theta + t)\}$$

where  $t$  is the minimal time until a transition becomes enabled, that is, the least  $t$  such that a guard on a transition from  $q$  is satisfied at  $\mathbf{x} + \mathbf{u}_q$ .

When there are immediate transition enabled in  $(q, \mathbf{x})$  we have

$$Succ(q, \mathbf{x}, \Pi, \theta) = L_1 \cup L_2 \cup L_3$$

where

$$L_1 = \{(q', \mathbf{x}', \Pi, \theta) : (q, \mathbf{x}) \xrightarrow{\tau} (q', \mathbf{x}')\}$$

for every immediate transition  $\tau$  such that  $\tau$  is non-conflicting or belongs to the job whose priority on the respective machine is higher than those of all competing jobs. In addition if there is a conflict on  $m$  involving a new job  $i$  whose priority compared to the highest priority job so far,  $i^*$ , has not yet been determined we have

$$L_2 = \{(q, \mathbf{x}, \Pi \cup \{i^* \prec i\}, \theta)\}$$

and

$$L_3 = \{(q, \mathbf{x}, \Pi \cup \bigcup_{\{i' : i' \#_m i\}} \{i \prec i'\}, \theta)\}.$$

The successor in  $L_2$  represent the choice to prefer  $i^*$  over  $i$  (the priority of  $i$  relative to other waiting jobs will be determined only after  $i^*$  terminates), while  $S_3$  represents the choice of preferring  $i$  over all other jobs.

Using this definition we can construct a search algorithm that explores all the efficient runs of  $\mathcal{A}$ .

**Algorithm 1 (Forward Reachability for Stopwatch Automata)**

```

Waiting :=  $\{(s, \mathbf{0}, \emptyset, 0)\}$ ;
while Waiting  $\neq \emptyset$ ; do
  Pick  $(q, \mathbf{x}, \Pi, \theta) \in \textit{Waiting}$ ;
  For every  $(q', \mathbf{x}', \Pi', \theta') \in \textit{Succ}(q, \mathbf{x}, \Pi, \theta)$ ;
    Insert  $(q', \mathbf{x}', \Pi', \theta')$  into Waiting;
  Remove  $(q, \mathbf{x}, \Pi, \theta)$  from Waiting
end

```

The length of the shortest path is the least  $\theta$  such that  $(f, \mathbf{x}, \Pi, \theta)$  is explored.

This is a brute-force search algorithm that can be improved into a best-first search as follows. We define an evaluation function for estimating the quality of configurations.

$$E((q_1, \dots, q_n), (v_1, \dots, v_n), F, \theta) = \theta + \max\{g^i(q_i, v_i)\}_{i=1}^n$$

where  $g^i$  is the previously-defined ranking function associated with each automaton  $\mathcal{A}^i$ . Note that  $\max\{g^i\}$  gives the most optimistic estimation of the *remaining* time, assuming that no job will have to wait. It is not hard to see that  $E(q, \mathbf{x}, F, \theta)$  gives a lower bound on the length of every complete run which passes through  $(q, \mathbf{x})$  at time  $\theta$ .

The modified algorithm now orders the waiting list of configurations according to their evaluation. This algorithm is guaranteed to produce the optimal path because it stops the exploration only when it is clear that the unexplored states cannot lead to schedules better than those found so far.

**Algorithm 2 (Best-first Forward Reachability)**

```

Waiting :=  $\{(s, \mathbf{0}, \emptyset, 0)\}$ ;
Best :=  $\infty$ 
 $(q, \mathbf{x}, F, \theta) := \textit{first in } \textit{Waiting}$ ;
while Best  $> E(q, \mathbf{x}, F, \theta)$ 
do
   $(q, \mathbf{x}, \Pi, \theta) := \textit{first in } \textit{Waiting}$ ;
  For every  $(q', \mathbf{x}', \Pi', \theta') \in \textit{Succ}(q, \mathbf{x}, \Pi, \theta)$ ;
    if  $q' = f$  then
      Best :=  $\min\{\textit{Best}, E((q', \mathbf{x}', \Pi', \theta'))\}$ 
    else
      Insert  $(q', \mathbf{x}', \Pi', \theta')$  into Waiting;
    Remove  $(q, \mathbf{x}, \Pi, \theta)$  from Waiting
end

```

With a best-first algorithm we were able to find optimal schedules of system with up to 8 jobs and 4 machines ( $12^8$  discrete states and 8 clocks). In order to treat larger problems we abandon optimality and use a heuristic algorithm which can quickly generate sub-optimal solutions. The algorithm is a mixture of breadth-first and best-first search with a fixed number  $w$  of explored nodes at any level of the automaton. For every level we take the  $w$  best (according to  $E$ ) nodes, generate their successors but explore only the best  $w$  among them, and so on.

In order to test this heuristics we took 16 problems among the most notorious job-shop scheduling problems.<sup>5</sup> Note that these are pathological problems with a large variability in

Table 2: The results of our implementation on the benchmarks. Columns #j and #m indicated the number of jobs and machines, followed by the best known results for non-preemptive scheduling, the known optimum for the preemptive case, the results of Le Pape and Baptiste, followed by our results and their deviation from the optimum.

step durations, constructed to demonstrate the hardness of job-shop scheduling. For each of these problems we have applied our algorithms for different choices of  $w$ , both forward and backward (it takes, on the average few minutes for each problem). In Table 4 we compare our best results on these problems to recent results reported by Le Pape and Baptiste [PB96, PB97] where the problem was solved using state-of-the-art constraint satisfaction techniques. As the table shows, the results our first prototype are very close to the optimum.

## 5 Conclusion

We have demonstrated that the automata-theoretic approach to scheduling can be extended to preemptive scheduling and be applied successfully to very large systems. Future work will investigate the applicability of this approach to scheduling of periodic tasks in real-time systems.
